## ABSTRACT

Using the deepest and finest resolution images of the Universe acquired with the Hubble Space Telescope and a similar image taken 7 years later for the Great Observatories Origins Deep Survey, we have derived proper motions for the point sources in the Hubble Deep Field–North. Two faint blue objects, HDF2234 and HDF3072, are found to display significant proper motion,  $10.0 \pm 2.5$  and  $15.5 \pm 3.8$  mas yr<sup>-1</sup>. Photometric distances and tangential velocities for these stars are consistent with disk white dwarfs located at  $\sim 500$  pc. The faint blue objects analyzed by Ibata et al. (1999) and Mendez & Minniti (2000) do not show any significant proper motion; they are not halo white dwarfs and they do not contribute to the Galactic dark matter. These objects are likely to be distant AGN.

*Subject headings:* dark matter—Galaxy: halo—stars: evolution—white dwarfs

## 1. Introduction

Major observational campaigns have searched for dark matter in the form of massive compact halo objects (MACHOs) using microlensing events (e.g. Alcock et al 1997; Afonso et al. 2003; Udalski et al. 1992). The detection of 13–17 microlensing events toward the Large Magellanic Cloud during 6 years by the MACHO collaboration implies that a significant fraction (20%) of the halo of the Galaxy may be in the form of compact halo objects (Alcock et al. 2000). The time scale of these lensing events eliminates the possibility of MACHOs having substellar masses. The MACHO collaboration finds a most probable mass of  $0.5 M_{\odot}$  which supports the idea of a massive halo comprised of baryonic matter in the form of low luminosity white dwarfs (Kawaler 1996). Recent observations by the EROS group provide further evidence that less than 25% of a standard dark matter halo can be composed of objects with a mass between  $2 \times 10^{-7} M_{\odot}$  and  $1 M_{\odot}$  (Afonso et al. 2003).

Halo white dwarf stars are expected to have large proper motions as a result of their high velocities relative to the Sun. HST proper motion studies of the Globular Cluster NGC 6397 showed that most of the required dark matter in the solar vicinity can be accounted for by a population of old white dwarfs representing the thick disk and halo of the Galaxy (Mendez 2002). Claims by Oppenheimer et al. (2001) and Ibata et al. (2000) that they had found a significant population of halo white dwarfs from kinematic surveys are tantalizing. Their discoveries seemed to be consistent with earlier findings of an old population of white dwarfs in the Hubble Deep Field (Mendez & Minniti 2000). However, further analysis by several groups showed that the sample of Oppenheimer et al. (2001) could also be interpreted as the tail of a kinematically warmer white dwarf component, better explained by the thick disk population of the Galaxy (Reid et al. 2001; Reyle et al. 2001; Mendez 2002; Bergeron 2003).

The Hubble Deep-Field (HDF) provides a unique window on the Universe (Williams et al. 1996; Flynn et al. 1996). The extreme depth of the HDF provides an unprecedented advantage to find faint stellar objects as well as to study very distant galaxies. The advantage of going deep is that it allows us to search for faint stellar components of the Galaxy in the regions of the color–magnitude diagram that are devoid of any contamination by standard Galactic stars. The lack of ordinary disk stars is due to the finiteness of the Galaxy (Flynn et al. 1996). Mendez & Minniti (2000) claimed that the faint blue objects found in the HDF–North and HDF–South are Galactic stars based on the observed number of blue sources and

extragalactic sources in the two fields. Independent proper motion measurements for five of these faint blue sources by Ibata et al. (1999) suggested that they are cool halo white dwarfs which could account for the entire missing mass in the solar neighborhood. Third epoch data on these five objects, however, did not show any significant proper motion (R. Ibata, private communication; Richer 2001).

We use the original Hubble Deep Field – North data and images of the same field taken 7 years later for the Great Observatories Origin Deep Survey (GOODS) to measure proper motions of the point sources analyzed by Ibata et al. (1999) and Mendez & Minniti (2000).

## 2. Proper Motion Measurements

GOODS is a multi-wavelength, multi-facility deep survey designed to study galaxy formation and evolution over a large redshift range. It includes deep imaging with ACS in the B, V, i, and z bands, and reaches down to  $AB = 28.1, 28.4, 27.7,$  and  $27.6$  in the four bands, respectively (10 sigma, point source) (Giavalisco et al 2003). Our second epoch data, acquired with HST and ACS as part of the GOODS ACS Treasury program, provide a baseline of 7 years. The GOODS team released version 1.0 of the reduced, calibrated, stacked, and mosaiced images of the HDF – North in 17 sections. Section 32 (total integrations of 34.9 ks in V and 36.9 ks in I) and section 33 (48.9 ks in V and 51.9 ks in I) overlap with the original HDF–North images.

The source catalogs for the first epoch are produced by the Space Telescope Science Institute (STScI) from the combined and drizzled images. We note that the first epoch HDF–North catalogue is based on rereduced HDF–North images by Casertano et al. (2000), providing a 10% increase in depth. We used the SExtractor package (Bertin & Arnouts 1996), version 2.3, to build source catalogues from the second epoch data. The major motivation for using SExtractor was its incorporation of weight maps in modulating the source detection thresholds. Source detection was carried out on the inverse-variance-weighted sum of the V and I band drizzled images. The combined V + I image is deeper than any of the individual images (Casertano et al. 2000). Only those objects matching the positions of the objects in the first epoch data with differences less than 0.2 arcsec are included in our final catalogue. Furthermore, we visually inspected all of the sources used for our proper motion study to avoid any mismatches. Although the GOODS Team released version r1.0 of the ACS multi-band source catalogs, their catalogs are based on z-band detection only (Giavalisco et al. 2004). Hence the released catalogs are not appropriate for the study of faint blue objects. The GOODS data are 0.5 – 0.8 mag shallower than the original HDF images, therefore we use the first epoch images for photometry. Astrometric and photometric data for the

point sources in the HDF–North are given in Table 1. We adopted the calibrated V and I photometry of Mendez & Minniti (2000).

Although the effective point spread function (ePSF) fitting procedure (Anderson & King 2000) is the most precise astrometric technique for HST images, well-exposed star images are required to accurately sample the PSF. There are not many stars in the Hubble Deep Field, and the main source of error in our proper motion measurements is the positions of the reference compact objects (galaxies). Therefore the ePSF method is not necessary and was not used for our analysis.

The original HDF images were rereduced and corrected for distortion by Casertano et al. (2000). The second epoch data were corrected for distortion by the GOODS team using the latest (July 2003) coefficients released by the ACS group at STScI. Even with these distortion corrections, however, some distortion remains (Bedin et al. 2003). The effect of the remaining distortion is larger if a global coordinate transformation is used. Instead of performing a global transformation, we have used the IRAF routine GEOMAP to derive a quadratic local transformation for each star, using a surrounding net of several dozen compact objects (isolated, low residuals, and not fuzzy). After mapping the distortions with the GEOMAP package, object coordinates were transformed to the second epoch positions with the GEOXYTRAN routine.

Figure 1 shows the contour maps for the two bright stars HDF2272 and HDF3072. The immediate field around each object is shown with dashed lines crossing at the first epoch position. The second epoch position is marked with an asterisk. This figure shows that SExtractor works very well for bright compact objects and these two objects are apparently moving. For faint objects pixel maps are more informative than contour maps. Pixel maps for two faint, possibly moving objects are shown in Figure 2. Solid lines cross at the first epoch position, and the second epoch position is marked with a box. Centroiding errors for faint stars are naturally worse, therefore proper motion errors are larger for the fainter stars.

### 3. Results

Proper motion measurements are mainly affected by distortion mapping and selection of reference objects. The RMS error of the transformations are larger than the positional errors of the objects. In order to check our distortion solution we have used the GEOMAP package with different polynomial terms. We started with no distortion correction and deleted deviant points using a  $3\sigma$  rejection algorithm. Rejection of very deviant points is required due to the fact that our reference objects are compact galaxies and centroiding errors

are larger for galaxies. We used quadratic, quadratic with one cross-term, and quadratic with 4 cross-terms local transformations. For most of the objects, the results from higher-order transformations were very similar to the results from the quadratic (with no cross-term) local transformation. This gave us confidence in the stability of our procedure. For two objects, the use of the higher-order terms made the distortion solution unstable because of the relative positioning of the reference objects. To be conservative, we adopted the quadratic with no cross-term local transformation for distortion mapping for all of our objects.

Figure 3 shows the differences between second epoch coordinates and transformed first epoch coordinates for one of our stars, HDF1583, and the surrounding 40 reference objects. A  $3\sigma$  rejection algorithm is later used to eliminate outliers from the sample. Error bars include positional errors from the SExtractor first and second epoch coordinates and the RMS error of the transformation. It is clear from this figure that HDF1583 is statistically well separated from the reference objects, most or all of which are galaxies: it is moving with respect to this external reference frame.

In order to further test our transformations, we have also used all compact objects with positional differences between the two epochs of less than 0.4 pixels to perform a global transformation. We found 377 compact galaxies matching our criteria, and fit a quadratic polynomial to map the distortions. As described above, we have measured proper motions in four to six different ways. Our conservative estimate of the proper motions, their significance ( $\mu/\sigma$ ), and position angle are given in Table 2, along with the observed range of proper motions from different transformation versions. A comparison of the observed ranges and errors for the proper motion measurements show that the errors are consistent with the variations between fitting techniques. Typical errors in our measurements are  $\sim 2.5$  mas yr<sup>-1</sup>. Hence, only those objects having proper motions larger than 5 mas yr<sup>-1</sup> have significance greater than two. The bright objects HDF2272, HDF2234, HDF101, HDF1583, HDF3072, HDF2258, and HDF1481 are definitely moving, and the faint objects HDF1816 and HDF774 might be moving.

Star-galaxy confusion becomes worse at faint magnitudes. Only objects  $15\sigma$  above the sky level were analyzed by Mendez & Minniti (2000). Proper motions provide further star-galaxy separation since anything with a significant proper motion cannot be very distant (e.g. Ibata et al. 1999).

We calculated photometric distances for all objects in our sample assuming that they are either main sequence stars, white dwarfs, or white dwarfs on the blue hook of the cooling sequence. For a given  $V - I$  color, we estimate three absolute magnitudes for each object by linearly interpolating the  $V - I$  and  $M_V$  relation for main sequence stars (Table 15.7 of Allen’s Astrophysical Quantities, 2000), white dwarfs, and cool white dwarfs (Hansen et al.

1999).

White dwarfs become redder as they cool until the effects of collision induced absorption due to molecular hydrogen becomes significant below  $\sim 5000$  K. The  $V - I$  colors for white dwarfs are expected to become bluer for  $T_{\text{eff}} \lesssim 3500$  K (Hansen et al. 1999; Saumon & Jacobson 1999). Cool white dwarf colors can be quite different in Johnson/Kron-Cousins and the HST filters since  $\text{H}_2$  opacity produces sharp flux peaks in the white dwarf spectra. The observed colors of the white dwarfs depend on the transmission peaks of the filters. Richer et al. (2000) calculated the HST colors for white dwarfs using the Holtzmann et al. (1995) bandpasses and the transformations they use to express fluxes in V, R and I. Hubble Deep Field photometry is calibrated using the Holtzmann et al. (1995) transformations (Mendez & Minniti 2000). Therefore we used Richer et al. (2000) white dwarf cooling tracks instead of more recent Chabrier et al. (2000b) models. We use the apparent magnitudes of the objects and the adopted absolute magnitudes to estimate photometric distances.

Proper motion measurements and derived distances can be used to calculate tangential velocities using the equation

$$\mu = \frac{V_{tan}}{4.74d} \quad (1)$$

where  $\mu$  is the proper motion in  $\text{arcsec yr}^{-1}$ ,  $d$  is the distance in parsecs, and  $V_{tan}$  is the tangential velocity in  $\text{km s}^{-1}$ . With the assumption that the objects are either main sequence stars, DA white dwarfs, or cool white dwarfs, derived distances and tangential velocities are given in Table 3. The differences between Chabrier et al. (2000b) and Richer et al. (2000) white dwarf colors are equivalent to absolute magnitude differences of 0 to 0.5 mag. This corresponds to 0–25% difference in estimated distances and velocities with an average difference of about 10%.

### 3.1. Bright Sources ( $V \leq 27$ )

Mendez & Minniti (2000) analyzed sources brighter than  $V=27$ , for which SExtractor gives reliable star–galaxy separation. The same sources have stellarity indices  $\geq 0.97$  in the GOODS data (Giavalisco et al. 2004) which has better spatial resolution than the original HDF images. The morphology of these sources as point–like is well supported. HDF2272, HDF2234, HDF101, HDF1583, HDF1828, HDF2134 and HDF2258 are further confirmed to be stars with Keck LRIS spectroscopy (Cohen et al. 2000).

We have searched the 503 X–ray point sources detected in the 2 Ms Chandra exposure of the region around the Hubble Deep Field North called the Chandra Deep Field North (Barger et al. 2003) for possible matches with the point sources analyzed here. We did not

find any objects matching our objects within a search radius of 0.5 arcseconds; we could not confirm if we had any quasars among our objects.

A comparison of the distances, tangential velocities, and photometric colors show that HDF1828, HDF2134, HDF2258, HDF1481, HDF684, and HDF3000 are halo main sequence stars (Table 3). Their  $V - I$  colors are too red to be white dwarfs. HDF2272, HDF101, HDF1583, and HDF1470 can be either main sequence stars or white dwarfs. Since we are sampling a larger volume for main sequence stars, these four stars are likely to be main sequence stars. Cohen et al. (2000) classified HDF2272 and HDF1583 as stars showing Mg absorption and Balmer lines, and HDF2234, HDF101, HDF1828, HDF2134 and HDF2258 as stars showing TiO or CaH bands.

HDF2234, HDF3072, HDF161, HDF3031, and HDF759 would have to be at very large distances and moving with velocities higher than the escape velocity of our Galaxy if they were main sequence stars. The first 11 objects ( $V \leq 26$ ) in Table 1 are also detected in the Hawaii-HDF-N Survey (Capak et al. 2003), an intensive multi-color (U, B, V, R, I, z, HK) imaging survey of 0.2 square degrees centered on the HDF-N. Figure 4 shows normalized  $UBVRIZ$  magnitudes for HDF2234 (filled triangles), HDF3072 (filled circles), and HDF161 (open circles) along with colors for a 15000 and 3000 K blackbody (long-dashed lines). The observed magnitudes are normalized at  $V$ . Dashed-dotted lines represent two DA white dwarf models (7000 K and 3500 K), and dotted lines represent two DB white dwarf models (8000 K and 3500 K; D. Saumon, private communication). Our simulations for a QSO at  $z=0.3$  (upper solid line) and another at  $z=0.7$  (lower solid line) are also shown. We have used the composite quasar spectra from the Sloan Digital Sky Survey (Vanden Berk et al. 2001) to simulate the colors for quasars. Plotting all of the normalized magnitudes in the same plot is an efficient way of presenting all of the data; it is similar to plotting low-resolution spectroscopy.

A comparison of the observed colors of HDF2234 with the models shows that it is hotter than 10000 K. J. Cohen kindly provided us the Keck/LRIS spectrum for HDF2234. The same object is also observed by the Team Keck Treasury Redshift Survey (Wirth et al. 2004) who made their data publicly available. Figure 5 shows the uncalibrated spectrum of HDF2234 observed by the Team Keck Treasury Redshift Survey. The object shows  $H\alpha$  at its rest wavelength; it is a star in our Galaxy. Although Cohen et al. (2000) classified this object as a late-type star showing CaH or TiO, its colors indicate that HDF2234 is too hot to show CaH and/or TiO. Absence of  $H\beta$  and Mg absorption eliminates the possibility of the object being a main sequence star. The broad feature at  $\sim 5400 \text{ \AA}$  might be due to the efficiency of the instrument + blocking filter combination, and the  $6890 \text{ \AA}$  feature is the atmospheric B band. The star could be a cool DA white dwarf showing only  $H\alpha$ . However, the colors

indicate that this should be a white dwarf hotter than 10,000 K which is inconsistent with such weak H lines, unless the star is a DC white dwarf at a position just too cool to show He I (11,000K) but then  $H\alpha$  alone cannot be explained. The nature of this object remains ambiguous at this time. Follow-up spectroscopy in the blue is needed to confirm that this object is a white dwarf.

HDF3072 displays even higher apparent proper motion than HDF2234,  $15.47 \pm 3.83$  mas yr<sup>-1</sup>. Its colors, and implied distance and velocity are consistent with a  $\sim 4500$  K white dwarf at  $d \approx 500$  pc.

The faint blue objects in Mendez & Minniti (2000) are HDF684, HDF161, HDF3031, HDF759, and HDF995. We have classified HDF684 as a main sequence star (see above). The rest of the faint blue objects, HDF161, HDF3031, HDF759, and HDF995 do not seem to exhibit any proper motion. HDF161 was near the detection limit of the Hawaii-HDF-N, and other three objects are not detected in the Hawaii-HDF-N. Figure 4 shows that HDF161 (open circles) exhibits a near-infrared excess; it is consistent with being a QSO under the given photometric uncertainties. Therefore we believe that HDF161, HDF3031 and HDF759 are probably AGN. These objects cannot be low-mass main sequence stars, brown dwarfs, or free floating planets due to their blue colors (see Chabrier et al. 2000a). Also, they cannot be comets or asteroids in our solar system due to their small proper motions (A. Cochran, private communication). Due to the large errors in the distance and velocity for HDF995, its nature is unclear.

### 3.2. Faint Sources ( $27 \geq V \geq 29$ )

Star-galaxy separation becomes ambiguous below  $V \approx 27$ . Proper motions can be used to identify stars fainter than 27th magnitude since a moving object has to be in our Galaxy. We find that only two of the objects in our sample, HDF1816 and HDF774, have significant movement. These two objects are most likely Galactic white dwarfs. The rest of the faint objects do not show any significant movement ( $\mu/\sigma \leq 2$ ). For these objects, distances and velocities are consistent with halo white dwarfs or extragalactic sources. Mendez & Minniti (2000) found 566 extragalactic sources in the same magnitude and color range as the 5 faint blue sources that are brighter than 27th magnitude. The ratio of the number of extragalactic objects to the number of stars increases at fainter magnitudes. Therefore, we believe that faint sources, with no significant apparent proper motion, are extragalactic objects.

### 3.3. Ibata et al. (2000) Objects

Ibata et al. (1999) obtained second-epoch exposures of the HDF in 1997, and derived proper motions using a 2-year baseline. They found that two blue, faint objects displayed proper motions  $\sim 25 \text{ mas yr}^{-1}$  and three other stars at the detection limit of the second-epoch observations might be moving. Third epoch data on these objects showed that these objects are not moving (R. Ibata, private communication; Richer 2001).

Two of the objects in the Ibata et al. (1999) sample are in common with Mendez & Minniti (2000) objects. These two objects, HDF806 and HDF1816, have stellarities larger than 0.9, therefore are classified as stars by SExtractor. Stellerity is the probability of an object being a point source (stellarity=1) or an extended object (stellarity=0) assigned by SExtractor. Mendez & Minniti (2002) found that all objects with stellarity  $< 0.85$  are clearly extended, and used a conservative cut at stellarity  $> 0.90$  to identify point sources. We find that HDF806 and HDF1816 have proper motions of  $1.15 \pm 2.91 \text{ mas yr}^{-1}$  and  $5.49 \pm 1.89 \text{ mas yr}^{-1}$ , respectively. The other three objects are classified as galaxies by the SExtractor. Visual inspection of the first and second epoch images (Figure 6) shows that these three objects are extended, and clearly not stars. We conclude that 3 of the objects (2-766, 4-141, 4-551) in the Ibata et al. (1999) sample are galaxies, HDF806 (2-455) is not moving, and HDF1816 (4-492) is probably moving ( $2.9 \sigma$  significance).

## 4. Discussion

The nature of the faint blue objects in the Hubble Deep Field may be crucial to understanding the contribution of low luminosity halo white dwarfs to micro-lensing events and the dark matter content of the Galaxy. Apparent proper motions for 5 faint blue objects (Ibata et al. 1999) was enough to explain the entire missing mass in the halo of the Milky Way. Mendez & Minniti (2000) claimed that the faint blue objects are white dwarf stars located at heliocentric distances of up to 2 kpc and belong to the Galactic halo. They found a local halo white dwarf mass density of  $4.64 \times 10^{-3} M_{\odot} \text{ pc}^{-3}$ , which would account for about 30–50% of the dark matter in the Galaxy.

With the advantage of a 7-year baseline, we are able to place better limits on the proper motion measurements of the faint blue objects. Using the proper motion information, we also derived distances and tangential velocities for these objects. Figure 7 shows the tangential velocities and distances for objects brighter than  $V \approx 27$  assuming that they are main sequence stars or DA white dwarfs. All of the main sequence stars exhibit halo kinematics and distances, whereas all of the likely white dwarfs exhibit disk kinematics and distances.

Following Gilmore, King, & van der Kruit (1989; see also von Hippel & Bothun 1990) we use the analytical form of the density profile for the thin disk and thick disk

$$\frac{\nu_0(z)}{\nu_0(0)} = 0.96 e^{-z/250pc} + 0.04 e^{-z/1000pc} \quad (2)$$

with a local normalization of  $0.11 M_\odot \text{ pc}^{-3}$  (Pham 1997). We use the form

$$\nu_{halo}(r) \propto \frac{\exp[-7.669 (R/R_e)^{(1/4)}]}{(R/R_e)^{(7/8)}} \quad (3)$$

for the halo (Young 1976), where  $R$  is the distance from the Galactic center, and  $R_e$  is the scale factor.  $R$  is related to the distance  $r$  from the observer to a star by

$$R^2 = R_0^2 + r^2 - 2rR_0 \cos b \cos l \quad (4)$$

with  $R_0$  the solar Galactocentric distance, and  $b$  and  $l$  the Galactic coordinates for the HDF–North. We use  $R_0 = 7.8 \text{ kpc}$  (Gilmore, King, & van der Kruit 1989),  $R_e = 2.7 \text{ kpc}$  (de Vaucouleurs & Pence 1978) and a local normalization for the halo of  $(1/800) \times 0.11 M_\odot \text{ pc}^{-3}$  (Chen et al. 2001; Gilmore, King, & van der Kruit 1989). Using equations 2, 3, and 4, we calculated the expected number of stars in the HDF. We expect to find 2 thin disk, 3 thick disk, and 11 halo objects in the HDF–North.

We have also used Reid & Majewski (1993) star count models to predict the number of stars in the HDF–North. We found that 2 thin disk, 4 thick disk, and 14 halo objects are expected in the HDF–North. Both simple analytical models and more sophisticated star count models, when extrapolated to the photometric depth of the HDF, predict similar number of stars (16–20) in the HDF–North.

There are 14 stars brighter than  $V = 27$  and 17 objects fainter than  $V = 27$  classified as stars by SExtractor. The observed number of stars and the predictions of star count models are in good agreement for  $V \lesssim 27$  (see also Mendez et al. 1996 and Mendez & Minniti 2000). On the other hand, there seems to be an excess of point sources in the Hubble Deep Field – North for  $V \gtrsim 27$ . Unfortunately, SExtractor classification cannot be trusted at these magnitudes. Furthermore, we did not detect significant proper motion for all but two of these objects. The two faint, possibly moving objects, HDF774 and HDF1816, may be halo white dwarfs. One of the problems with any analysis using these objects is that the observations are beyond the completeness limit, and any calculation based on them is subject to a significant completeness correction. The rest of the objects fainter than  $V = 27$  are probably extragalactic objects (see section 3.2).

The five faint blue objects analyzed by Mendez & Minniti (2000) do not exhibit any significant proper motion; they are not halo white dwarfs. These objects do not account

for the MACHO optical depth and are not the source of the Galactic dark matter. Their stellar nature is not confirmed either. The colors of HDF161 are consistent with our QSO simulations. The faint blue objects may be distant AGN.

Holberg et al. (2002) used a local sample of white dwarfs complete out to 13 pc, and found the local mass density of white dwarf stars to be  $3.4 \pm 0.5 \times 10^{-3} M_{\odot} \text{ pc}^{-3}$ . Using this normalization factor in equations 2 and 3, we estimate the expected number of white dwarfs in the Hubble Deep Field. We expect to find 0.05 disk white dwarfs, 0.09 thick disk white dwarfs, and 0.33 halo white dwarfs in the Hubble Deep Field North. We have also used Reid & Majewski (1993) star count models to predict the number of white dwarfs in the HDF. The results are roughly consistent: 0.10 disk, 0.25 thick disk, and 0.5 halo white dwarfs are expected.

We have discovered two likely white dwarfs, HDF2234 and HDF3072, brighter than  $V = 27$  in the HDF–North. They are located at distances of  $\sim 500$  pc and have tangential velocities  $\sim 30 \text{ km s}^{-1}$ . Their kinematic properties are consistent with being thin disk or thick disk objects (see Table 3 and Figure 7). The expected number of thin disk + thick disk white dwarfs is found to be 0.14 – 0.35. We have found 6 to 14 times more disk white dwarfs in the HDF–N than expected from the models. Assuming Poisson statistics, the probability of finding two white dwarfs is 1% if the expected number of white dwarfs is 0.14 and 4% if the expected number of white dwarfs is 0.35. The number of disk + thick disk white dwarfs may be substantially underestimated. Due to small number statistics, however, this statement is only a 2–3  $\sigma$  result and it heavily depends on the fact that HDF2234 and HDF3072 are white dwarfs. Follow–up spectroscopy of these two objects is needed to confirm this result.

Mendez & Minniti (2000) have found 22 Galactic stars and 10 faint blue objects in the Hubble Deep Field – South. A natural test to check the space density of disk and halo white dwarfs would be to obtain second epoch observations of the HDF–South to find high proper motion objects. Also, the HST/ACS Ultra–Deep Field observations of the Chandra Deep Field – South will be useful to search for faint blue objects at fainter magnitudes and to improve the morphological classification of these objects at brighter magnitudes. The Ultra–Deep Field will be  $\sim 1.5$  mag deeper than the HDF and HDF–South (Beckwith et al. 2003).

We thank Judy Cohen for kindly providing us Keck/LRIS spectrum of HDF2234. We also thank Didier Saumon for making his cool white dwarf models available to us and to the Team Keck Treasury Redshift Survey for making their data publicly available. We are grateful to J. Liebert & A. Cochran for useful discussions on the nature of HDF2234. This material is based upon work supported by the National Science Foundation under Grant No.

<sup>a</sup>Chip coordinates from the HDF mosaics

<sup>b</sup>Chip coordinates from GOODS section 33

<sup>c</sup>Chip coordinates from GOODS section 32

<sup>d</sup>Object in common with Ibata et al. (1999)

Note. — There is an offset between our coordinates and the GOODS Teams r1.0 version of the source catalogues (Giavalisco et al. 2004). The offset is +300 pixels in X and +200 pixels in Y.

Table 2. Proper Motions

Object	$\mu(\text{mas/yr})$	$\sigma$	$\mu/\sigma$	$\mu(\text{range})$	Pos. Angle
HDF2272	8.95	2.48	3.61	8.30–10.09	227.0
HDF2234	10.05	2.46	4.09	8.67–11.08	298.3

<sup>1</sup>Assuming that the object is either a main sequence star (MS), a white dwarf (WD), or a very cool white dwarf (CWD,  $T_{eff} \lesssim 3500K$ )<sup>2</sup>Distances are in parsecs, and velocities are in  $\text{km sec}^{-1}$

Fig. 1.— Two bright, apparently moving objects. The panels show contour maps and first and second epoch positions of the stars HDF2272 and HDF3072. The contour maps show the flux distribution around each object (20 x 20 pixels, 0.6" x 0.6"). Dashed lines cross at the first epoch position. An asterisk marks the second epoch position.

Fig. 2.— Two faint, possibly moving objects. The left panels show pixel maps for the first epoch and the right panels show pixel maps for the second epoch for HDF1816 and HDF774. Solid lines cross at the first epoch position. The second epoch position is shown with a box. Images are 20 pixels on a side (0.6").

Fig. 3.— Difference between second epoch coordinates ( $X_2, Y_2$ ) and transformed first epoch coordinates ( $X_1, Y_1$ ) for HDF1583 and the surrounding reference compact objects. Reference objects that are not included in our transformations are shown as open circles. Error bars include centroiding errors from the first and second epochs, and the RMS error of the GEOMAP transformation. HDF1583 is an example of an object that is clearly exhibiting proper motion.

Fig. 4.— Normalized  $UBVRIZ$  magnitudes for HDF2234 (filled triangles), HDF3072 (filled circles), and HDF161 (open circles). The observed magnitudes are normalized at  $V$ . The colors for a 15000 and 3000 K blackbody are shown as long-dashed lines. Dashed-dotted lines represent two DA white dwarf models (7000 K and 3500 K), and dotted lines represent two DB white dwarf models (8000 K and 3500 K, D. Saumon, private communication). Colors for a QSO at  $z=0.3$  (upper line) and another at  $z=0.7$  (lower line) are also shown as solid lines.

Fig. 5.— Keck/DEIMOS (un-calibrated) spectrum of HDF2234 observed by the Team Keck Treasury Redshift Survey. The spectrum is smoothed with a 5 pixel wide boxcar. Instrument efficiency for the blocking filter used for the observations is shown as dotted line. The broad feature at  $\sim 5400 \text{ \AA}$  is due to the instrument efficiency and the feature at  $6890 \text{ \AA}$  is the atmospheric B band. The only detectable feature is  $H\alpha$ .

Fig. 6.— Pixel maps for three of the Ibata et al. (1999) objects, HDF2837, HDF2952, and HDF574 with stellarity indices of 0.68, 0.07, and 0.11 respectively. Visual inspection of the images further confirms that these are extended objects. Note that we have not measured proper motions for these objects.

Fig. 7.— Tangential velocities and distances for main sequence stars (top panel) and likely white dwarfs (bottom panel) brighter than 27th magnitude. The dashed line marks the upper bound for the escape velocity from the Milky Way ( $650 \text{ km sec}^{-1}$ ; Leonard & Tremaine 1900; Meillon et al. 1997). All of the main sequence stars have halo properties, whereas the

probable white dwarfs have disk properties.
